18. SUPPLEMENTARY NOTES DRCMS Code: 612114.H730011 HDL Project No.: 304 734		
19. KEY WORDS (Continue on reverse side if necessary and identify by block number) Fluidics, Sensors, Proximity Sensors, Rate Gyros, Accelerometers, Flow Meters, Densitometers, Temperature Sensors, Concentration Sensors, Pressure Ratio Sensors.		
20. ABSTRACT (Continue on reverse side if necessary and identify by block number) The operational and physical characteristics of fluidic sensors are pre- sented. Emphasis has been placed on those devices that are commercially available. The format is arranged so as to provide system designers with detailed data necessary to determine whether a particular device can be employed in a given system. For each sensor, manufacturer, data source, and point of contact are also listed.

PREFACE

Presented herein is a survey of fluidic/flueric sensors that are commercially available or have reached an advanced development stage. Please note that neither the U.S. Government nor LORELEI Corporation advocates the use of any of the products described in this document. Rather, the manual is a factual listing of the operational and physical characteristics of representative fluidic components, compiled from data received from sources that responded to LORELEI queries.

This work was performed under the auspices of the Joint Logistic Commanders' Joint Technical Coordinating Group on Fluidics (JTTCG-Fluidics). The effort was cosponsored by the Harry Diamond Laboratories and Naval Air Systems Command.

LORELEI Corporation wishes to thank Mr. Richard Gottron and Mr. James Joyce of the HARRY DIAMOND LABORATORIES for their assistance and direction during the preparation of this manual. We also wish to thank all those manufacturers and government personnel who took the time to respond to our detailed questionnaire.

1. INTRODUCTION

1.1 General

Since the early 1960's, considerable effort has been expended by many investigators to quantify the operating characteristics of fluidic/flueric systems. However, despite extensive research, only a relatively small number of different types of components have been developed by commercial manufacturers. In general, the types of fluidic components commercially available fall into four main categories:

- Sensors
- Interface Devices
- Logic Devices
- Control Devices

These areas represent a broad spectrum of applicability for fluidic/flueric components; however, this report is pertinent only to sensors.

1.2 Statement of Problem

In broad terms it is convenient to define a sensor as any device that receives an input signal and provides a proportional output signal. This can be easily seen in the diagram presented in Figure 1.1. The input variable may be a motion (i.e., linear and angular displacement, velocity, or acceleration) or a characteristic of the medium (i.e., pressure, temperature, humidity, gas concentration, flow rate, etc.) Regardless of the input, the output of a fluidic sensor is typically a pressure or flow signal which may be analog, digital, or digital proportional (i.e., oscillating). This wide variation of both input and output parameters leads to a rather complex array of components especially since some can perform more than one sensing function.

As a further complication, sensors in general and fluidic sensors in particular are most always "size" dependent. Therefore, the geometric characteristics of a sensor designed to measure a specific parameter in a fluid

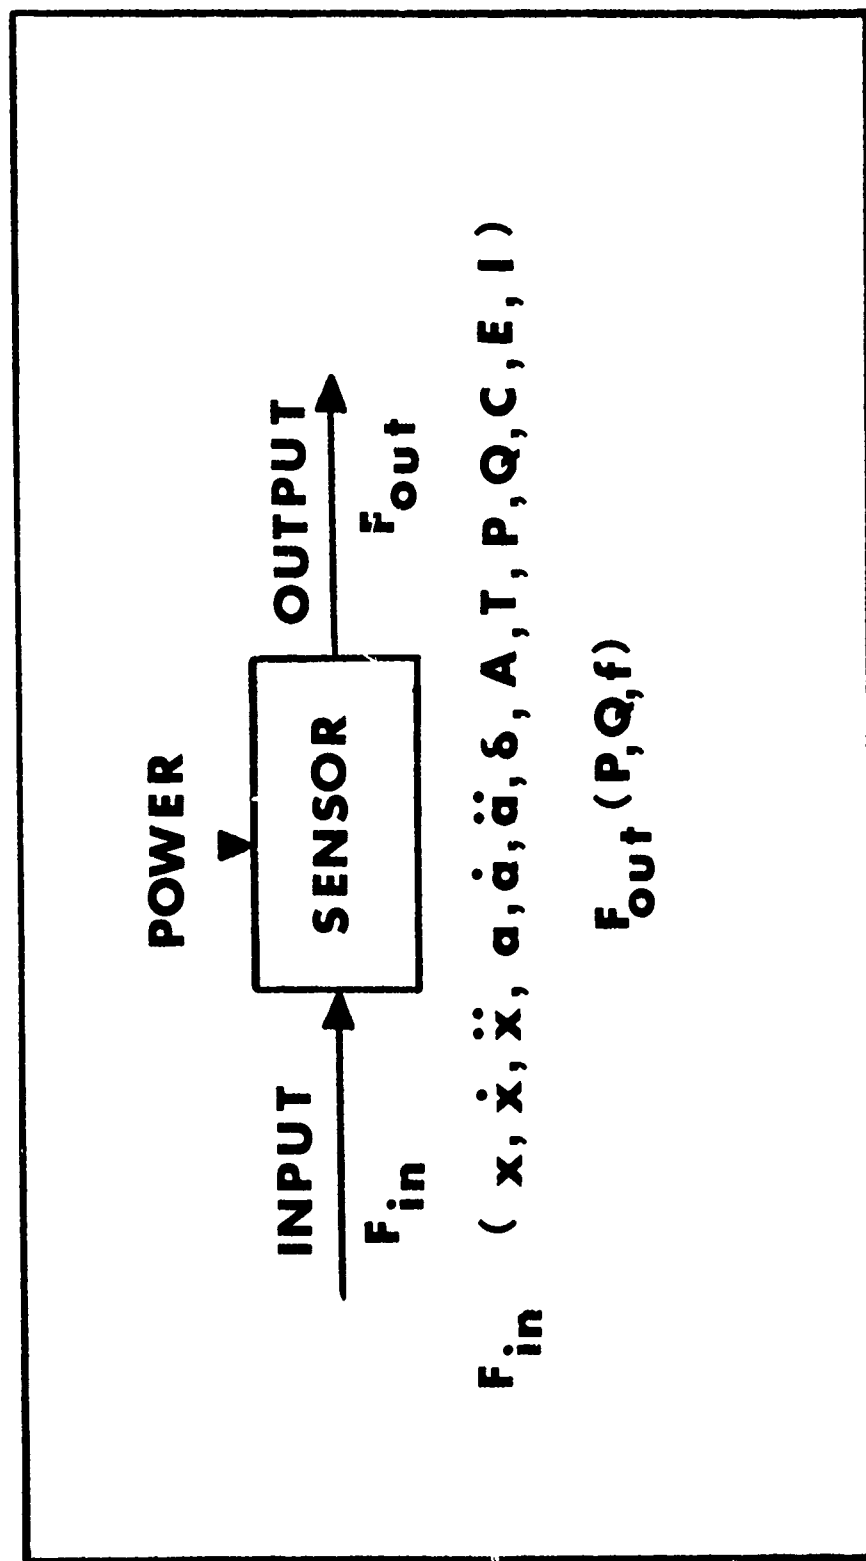

FIGURE 1.1 BLOCK DIAGRAM OF FLUIDIC SENSORS

medium flowing at a rate of 1 scfm, may require complete redesign in order to utilize the same sensor in a medium flowing at a rate of 10 scfm. Thus, one of the common problems facing system designers is that data cannot always be directly extrapolated from a single laboratory test, to a wide range of other situations.

1.3 Objective

Although fluidics has been recognized for over a decade as offering promise in the areas of sensing and classification of the sensed function, the industry in general has experienced difficulty in universally applying the technology. As mentioned, the prime reason for this is that a component designed for a specific application may require complete redesign for a similar application which requires a much larger or much smaller sensing element. One common solution employed by major manufacturers is to no longer offer individual components, but only offer a tailored design for a total system which would employ their unique sensing and logic elements. To some degree, this perpetuates the problem of fluidic system development. Conversely, many commercial manufacturers who provide components for general use by the industry typically do not provide enough system design information to allow their components to be used easily by non-fluidics oriented personnel.

The objective of this manual, therefore, is to provide to system designers (both fluidic and non-fluidic oriented) a basic compendium of the state-of-the-art technology of fluidic sensing elements. The manual provides detailed information (where possible) on the operating characteristics of the sensors, i.e., input parameters, output parameters, impedance matching requirements, etc. The ultimate goal of this manual, therefore, is not to provide the average individual the necessary background to design fluidic sensors, but rather to supply the system designer with enough information so that he can utilize state-of-the-art fluidic sensors in his present system as a replacement for other sensors which may be purely mechanical or electronic in nature.

medium flowing at a rate of 1 scfm, may require complete redesign in order to utilize the same sensor in a medium flowing at a rate of 10 scfm. Thus, one of the common problems facing system designers is that data cannot always be directly extrapolated from a single laboratory test, to a wide range of other situations.

1.3 Objective

Although fluidics has been recognized for over a decade as offering promise in the areas of sensing and classification of the sensed function, the industry in general has experienced difficulty in universally applying the technology. As mentioned, the prime reason for this is that a component designed for a specific application may require complete redesign for a similar application which requires a much larger or much smaller sensing element. One common solution employed by major manufacturers is to no longer offer individual components, but only offer a tailored design for a total system which would employ their unique sensing and logic elements. To some degree, this perpetuates the problem of fluidic system development. Conversely, many commercial manufacturers who provide components for general use by the industry typically do not provide enough system design information to allow their components to be used easily by non-fluidics oriented personnel.

The objective of this manual, therefore, is to provide to system designers (both fluidic and non-fluidic oriented) a basic compendium of the state-of-the-art technology of fluidic sensing elements. The manual provides detailed information (where possible) on the operating characteristics of the sensors, i.e., input parameters, output parameters, impedance matching requirements, etc. The ultimate goal of this manual, therefore, is not to provide the average individual the necessary background to design fluidic sensors, but rather to supply the system designer with enough information so that he can utilize state-of-the-art fluidic sensors in his present system as a replacement for other sensors which may be purely mechanical or electronic in nature.

1.4 Overview

The material presented within this manual is pertinent primarily to those sensors that are commercially available either as off-the-shelf or special order components. Also delineated to a lesser degree are sensors currently under development or being researched by government R&D labs, by industry, or by universities. Most detailed information has been obtained on commercial sensors, and it is upon these parameters that the system designer should base his system design. However, in the event the function cannot be performed adequately by commercial fluidic components, and/or the particular system for which the element is being considered is in the R&D stage, then obviously the system designer should consult the material detailing sensors currently under development.

The section is subdivided into specific areas containing detailed information on each sensor. Information was acquired by an extensive literature survey, which commenced with a questionnaire sent to approximately 500 organizations (manufacturers, government agencies, and universities) located both within and outside the United States. A copy of the questionnaire is included as Appendix A. Approximately 35% of the contacts responded in part to the questionnaire. Their responses consisted of filling out the questionnaire and providing the supplemental information or simply mailing the marketing information they commonly supply in advertising literature. As a result, the material presented in this report is not consistent for each sensor. However, a point of contact is indicated in most cases to allow the reader to obtain other detailed information directly from the source. It should be noted that the emphasis herein is placed primarily upon substantiated data, and laboratory tests of prototypes or research devices are labeled as such.

2. COMMERCIALLY AVAILABLE SENSORS

2.1 General

Fluidic sensors, in general, can be categorized several ways. For convenience, however, they are usually classified either according to their function or according to their design. The latter designation may be confusing. For example, a vortex sensor may be used to detect angular rate, temperature, or gas concentration. Therefore, to eliminate confusion in the following discussion, the categorization is first made according to the function of the sensor, and then according to the type of sensor within each of these categories. Breakdowns according to function are:

- Proximity Sensors
- Angular Rate Sensors
- Accelerometers
- Temperature Sensors
- Concentration Sensors
- Miscellaneous Sensors

As stated in the Introduction of this manual, a discussion of each generic type of sensor and of each particular type of sensor has been prepared in accordance with the information received from the questionnaires sent to the various sources. As such, the presentation of pertinent material varies slightly from sensor to sensor, depending upon the responses received. The format for each sensor investigated remains consistent throughout the report. Note that the term (NA) is used to indicate items which are not applicable to a particular sensor. Where data were not provided, a (U) for "unspecified" is utilized. Logic symbols are those used by each manufacturer.

2.2 Proximity Sensors

Proximity sensors are devices which provide either an analog or digital output signal that is dependent upon the juxtaposition of an object passing by the sensor. The two basic types of proximity sensors are non-

contact and contact. With a non-contact sensor, a jet stream is usually aimed across a gap. When that stream is interrupted by an object entering the gap, a resultant change in output pressure and flow occurs. A diagram of both variations of the basic proximity sensor theme is shown in Figure 2.1. In Figure 2.1a, a jet stream impinges against the moving object, causing an output signal in the form of a back pressure change. In Figure 2.1b, an object would pass by the flowport, labeled "C." Depending upon the proximity of C to the sensor, either full or partial flow differentiation will take place between D_1 and D_2 . If the flow switches completely from D_1 to D_2 , the device is known as a digital (on-off) sensor. If the flow rate is proportional between D_1 and D_2 (to the distance of the object from C), then the device is known as a proportional sensor. It should be noted that a pushbutton (where a finger can be used as the flapper of the valve as shown in Figure 2.1a) is the simplest type of proximity sensor. Variations of this basic element are referred to by manufacturers as "key" or "back pressure switches." Detailed information on all of the various types of proximity sensors follows.

FIGURE 2.1 BASIC PROXIMITY SENSOR OPERATION

2.2.1 Cone-Jet Proximity Sensor

The cone-jet proximity sensor employs an annular nozzle connected to a supply port as shown in Figure 2.2. The annular sensing nozzle surrounds an output port and, if not interrupted, the air flow forms a conical jet, thus creating a negative pressure at the output. When an object passes through the cone region of the jet, the normal sub-atmospheric region becomes one of positive pressure due to the supply jet being deflected from the intruding object into the low pressure region. The result is a high pressure output signal, the magnitude of which is inversely proportional to the spacing between the object and the annular nozzle. Manufacturers claim that there are no "overtravel" problems such as are encountered with conventional limit switches and valves, and the device is ideal for conditions where physical contact could cause damage to the parts. Flat or curved objects up to .25 in from the nozzle can be sensed. It should be noted that this type of proximity sensor requires at least a .25-in-square surface for positive activation and, therefore, does not lend itself to sensing wires or other small objects.

2.2.2 Vortex Proximity Sensor

The basic operation of a vortex proximity sensor is shown in Figure 2.30. The vortex chamber is used to generate a swirling flow in the shape of a diverging cone. This high-velocity vortical flow entrains ambient air, thereby maintaining essentially atmospheric pressure within the cone. At the vertex of this cone is a sensing/output port. The introduction of any object in the conical region restricts the replenishment of the entrained flow, and a local pressure reduction occurs. The resultant signal is negative pressure, relative to that which existed for the sensor in an unobstructed state. With a vortex proximity sensor, the output is analog and is inversely proportional to the gap between the sensor and the object. Because of the low gain of this type of sensor, the device is usually coupled to a high gain amplifier, or if a digital signal is required, to a Schmitt trigger.

One of the largest drawbacks with this type of system is that the output depends upon entrained air from the atmosphere, thus introducing a high probability of contamination of the sensor. Commercial manufacturers claim, however, that this is not a severe problem since positive output pressures tend to prohibit contaminants from entering the internal parts of the system. Further, periodic cleaning can minimize any contaminant buildup. Manufacturers claim that the maximum sensitivity range of a vortex sensor is in the order of 0.5 to 0.75 inch. The minimum object size required is 0.375 inch square, and thus the sensor does not lend itself to sensing wire or any other extremely small object.

2.2.3 Annular Nozzle Proximity Sensor

A longer range sensor, which employs a variation of the basic principles of the cone-jet and vortex devices, uses a diverging, swirl-free annular nozzle. Jet entrainment causes this divergent conical flow to converge at some distance from the nozzle. Within the oval thus formed as shown in Figure 2.33, the pressure is substantially reduced and when this low pressure pattern becomes disturbed by an obstruction, an abrupt pressure bubble burst takes place and the pressure becomes that of atmospheric. To accentuate the sudden pressure rise, the pressure sensing port is situated within the bubble near the point where the jet makes its sharpest turn. When the bubble breaks, the jet shifts away from the output opening therefore inducing a maximum pressure rise.

Because this device employs a pressurized power supply (and essentially no atmospheric air is entrained), it is relatively contamination free. Manufacturers claim that the maximum sensitivity range of this type of sensor is approximately 1.125 inches, and that this distance is relatively independent of changes in supply pressure. Unfortunately, with this type of sensor only a relatively large object can be sensed, i.e., on the order of 1.5 inchessquare; therefore, the device does not lend itself to applications such as sensing a wire or even serving as an edge guide mechanism.

2.2.4 Interruptible Jet Proximity Sensor

The interruptible jet sensor is one of the most common of all the fluidic proximity sensors currently available. Variations of its basic principle of operation are shown in Figure 2.37. It is by far the simplest in concept since it requires only a supply tube and a coaxial receiver tube separated by a specific gap region. With no object interrupting the flow supply through this gap, the pressure recovered in the receiver is nearly equal to that of the supply (with minimum losses due to gap spacing). The insertion of any object in the gap reflects and/or impedes supply flow to the receiver thus causing a pressure drop for the device shown in Figure 2.37a, or a pressure increase for the device shown in Figure 2.37b.

Manufacturers claim that the interruptible jet sensor will sense any flat or round object with a .032 in. minimum radius within a maximum sensitivity range of 0.5 inch. There are two basic configurations of the interruptible jet sensor. In Figure 2.37a, the output signal is due to air captured by the receiver, and contamination may occur due to entrainment of ambient air along with the jet. In Figure 2.37b, the sensor emits flow from both the emitter and the receiver. Since ambient air is not entrained, the possibility of contamination is minimized. It is also possible to employ a technique known as "cross-fire," whereby a jet is placed at a 90° angle to the interruptible jet emitter and receiver. The use of this technique is dependent upon such factors as the size of the object, the supply pressure to the primary jet, and the sensitivity of the switching element.

2.2.5 Acoustic Proximity Sensor

The acoustic sensor (commonly referred to as the Fluidic Ear) is fluidic technology's counterpart of the photoelectric eye. Its principle is based upon the fact that the coherence of an air jet may be interrupted by a high frequency sound (typically in the order of 50 kHz). Basically, the fluidic ear contains two components, an emitter (or sender) and the receiver. The emitter projects the 50 kHz beam across the sensing gap, and the receiver (a digital/fluid amplifier) is interrupted by that acoustic beam. The separation between the sound emitter and receiver may be as large as 60 in. with response times as low as 2 ms. An additional advantage of this sensor over the simple interruptible jet is that the sound may be reflected so that the supply and the receiver need not be colinear. Thus, the unit may be designed to cover a rather large area. Manufacturers claim that by using interferometric techniques, a resolution of displacement as small as 0.10 in. may be detected. It should be noted that the fluidic ear sensor is not affected by random frequencies (other than the narrow band near 50 kHz) and, thus is tolerant to vibration and shock over a wide range of temperatures and supply pressures. Two modes of operation are shown in Figure 2.69.

2.2.6 Hybrid Proximity Sensors

The application of any of the preceding components may be used in conjunction with several other types of fluidic devices to close ports, make electrical contacts, provide a force output, and/or effect an interface with another fluid. Several such hybrid proximity sensing devices are on the market. Some devices utilize a low force contact element such as a spring to provide a positive contact with the device being sensed. The output of this type of unit is much greater than any of the previously discussed purely fluidic elements and is usually analog. Since the output flow is directly proportional to the deflection of the spring, the curve of output signal vs force is usually linear.

Other variations of the basic device employ a fluidic sensor in consort with a diaphragm to convert the signal into either an electrical or a mechanical output. Several of these components are used in regions where it is impractical or unfeasible to employ fluidic staging elements to achieve the required signal amplification. A spring actuated device is shown in Figure 2.72.

2.3 Angular Rate Sensors

Angular rate sensors are devices which measure the speed of rotation of an object about its axis. In general, this speed of rotation is directly proportional to the output signal generated by the sensor. Typical applications include measurements of the speed of a shaft, the speed of a gear system, and the angular rate of pitch or yaw of a vehicle. In the former cases the sensor does not rotate, but measures the speed of rotation externally. In the latter case (vehicle motion), the sensor itself is part of the rotating system and can be configured as shown in Figure 2.76.

Most angular rate sensors are not available commercially as off-the-shelf components, but are usually offered by manufacturers as part of an overall system tailored to a specific application. As such, each of the components presented in the following section is pertinent to a special application and should not be construed as being universally applicable to any system requiring an angular rate sensing element.

2.3.1 Impulse Angular Rate Sensor

This type of sensor is based upon the principle of employing an interruptible jet to sense the separation between an emitter and the receiver as the jet is fragmented by a gear or other segmented wheel. This concept is shown in Figure 2.78. As the wheel rotates, the jet is interrupted continually, forming a pulse train whose frequency is linearly related to the shaft RPM. Care must be taken when designing such a system to ensure that the pulse train frequency is such that for a given rotational speed, the receiver or the interruptible jet sensor is not saturated (i.e., frequencies so high that the impulses are not easily discernible, but appear merely as a ripple on a DC steady state signal output). Virtually any of the interruptible jet sensors presented in Section 2.2.4 of this report can be used in conjunction with a gear to form an impulse type angular rate sensor. Note, the boundary layer type of angular rate sensor shown in Figure 2.78 operates on the same principle; however, no commercial devices exist which employ this principle.

FIGURE 2.80 AVAILABLE DATA: PROPORTIONAL SHAFT RATE SENSOR - HONEYWELL

2.3.2 Vortex Angular Rate Sensor

The vortex angular rate sensor is based on the principle of conservation of angular momentum. It has a geometry similar to that shown in Figure 2.73 and is particularly useful when the angular rate to be sensed is small or the range of the rate to be sensed is extremely large. As shown, fluid enters the device tangentially, thus creating an initial fluid rotation through the vortex chamber prior to flowing out of the drain. Any angular rotation about the axis of the device is "added" to the tangential component of the flow thereby inducing a larger or smaller vortex depending upon the direction of body rotation relative to the initial vortex generated in the device. The sensitivity of this device is highly dependent upon the pickoff type, number, and construction, and although it has probably undergone more development than any other type of sensor, problems still include drift and hysteresis. Claims for sensitivities range from a threshold of 1/10 of a degree per second to a full scale range of 3000 degrees per second.

A variation of the device based upon laminar flow has been developed in an attempt to improve signal to noise ratio characteristics. Unfortunately, no devices of this type are commercially available as off-the-shelf components. However, several have been developed as specialized items for specific system application.

2.3.3 Hybrid Systems

For the purposes of this manual, hybrid systems are defined as those which employ either electrical or mechanical components in the system or some combination of the phenomena previously addressed by the other sensors. For example, the effect of Coriolis forces on a laminar jet has been used as the basis for a sensor having an electrical pickoff. Thermistors connected to a bridge circuit cause a jet to deflect proportional to the rotation of the unit. The flow of the laminar jet is generated by oscillations of a Piezoelectric crystal making the unit totally independent of an external air supply. Manufacturer claims for this system are that the output is extremely linear and that the unit can withstand shocks in excess of 1000 G's. However, because of its geometry, it appears that it may be responsive to linear accelerations along the axis of the pumping element. A representative unit is shown in Figure 2.83.

2.4 Accelerometers

Accelerometers are basically defined as devices that yield an output signal as a function of the acceleration of the device itself. With the exception of one device currently in the development stage, nearly all accelerometers are fluidic and not flueric in nature. Fluidic accelerometers, which by definition eliminate the solid proof mass and use a purely fluid phenomenon, are still in the development stage. Difficulties have been encountered trying to derive a large output signal from the fluid. Thus, in the material presented for each of the following fluidic accelerometers, all described components have a minimum number of moving parts and use a substance of substantially different density to provide the accelerometer function. An example of a fluidic accelerometer is shown schematically in Figure 2.86.

FIGURE 2.86 BASIC FLUIDIC ACCELEROMETER OPERATION

2.4.1 Seismic Mass Accelerometer

A seismic (proof) mass accelerometer in its simplest concept consists of the arrangement schematically depicted in Figure 2.87. Although there are several variations of this type of accelerometer, only an elementary concept is depicted. Basically, a continuous flow of gas enters the supply ports, and output flows and pressures are monitored. As the component is accelerated, the proof mass tends to remain stationary due to inertia. This relative movement causes a net change in the spacing between the proof mass and the walls of the casing, thus changing the resistance across the outputs and causing a pressure differential. The pressure differential balances the inertial force, and the output, $P_1 - P_2$, is nearly linear with regard to the acceleration. A constant scale factor is obtainable by manipulating the geometry and mass of the sensor. It should be also noted that to minimize the effect of static friction, the proof mass is usually supported by an air bearing. A variation of this concept is to support the proof mass by flexible cables, rather than an air bearing.

Typically, manufacturers have claimed fabrication of fluidic accelerometers having ranges of up to 400 G's with threshold frequencies in the order of 0.02 psid/G. They operate at supply pressures from 20 to 2200 psig, and output pressure levels, depending on the type of device, can range from 20 to 70% of the supply pressure. It should be noted also that all seismic mass accelerometers are analog devices.

2.4.2 Vibrating String Accelerometer

The vibrating string accelerometer employs a spring loaded proof mass which changes a feedback loop of a fluidic oscillator as a function of acceleration. A diagram of the basic concept is shown in Figure 2.90. Each accelerometer consists of the following components: a round wire, wire terminations, attenuation spring, the seismic mass, the input pressure nozzle, and the receiver nozzle.

The basic operation of this type of device is dependent on the phenomenon known as Strouhal or vortex shedding. Each nozzle impinges on a wire and the resultant vortex shedding creates an alternating pressure field which excites the wire in its natural mode of oscillation. Therefore, the nozzle flow is periodically interrupted by the wire motion, and a sinusoidal pressure pulse is detected by the receiver. These sinusoidal pulses are then fed into a beat frequency detector element, and the modulated pressure signal containing both the sum and difference frequencies are obtained. Experiments which have been conducted show that the Strouhal frequency (i.e., resonant frequency) of the wire is directly proportional to the square root of the tension in the wire itself. Further, as acceleration is applied along the input axis of the device, the tension of the wire effectively changes and, by measuring the beat frequencies, a signal is obtained that is directly proportional to the acceleration applied to the device. Note that the vibrating string system is basically a digital output accelerometer with signal proportional to the frequency shift.

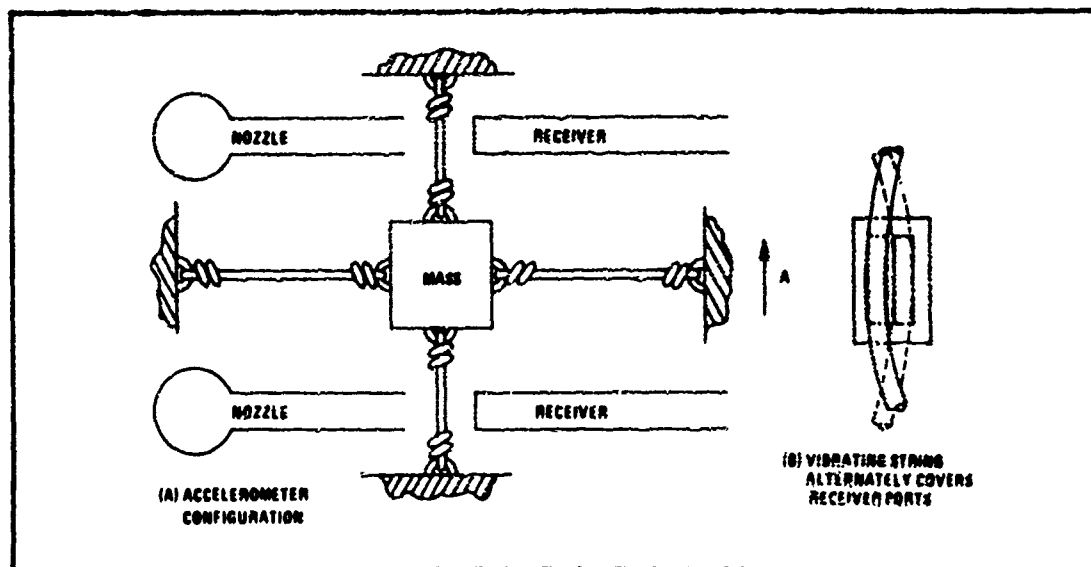

FIGURE 2.90 BASIC VIBRATING STRING ACCELEROMETER OPERATION

2.5 Temperature Sensors

One of the environmental parameters that can drastically alter the performance of any fluidic/flueric type of device is temperature. This has been used to advantage by many inventors and manufacturers to develop fluidic devices which sense temperature by monitoring both viscous and/or acoustic phenomena. Extensive testing and use of fluidic sensors in military aircraft have indicated that these devices have response characteristics of approximately 10 milliseconds.

Fluidic temperature sensors can be both analog or digital in nature. However, there are two basic methods by which the temperature of a fluid may be measured. The first technique (which usually yields the fastest response time) is to allow the fluid itself to pass through the measuring device. The second technique is to utilize the sensor as a probe inserted in the fluid medium. A typical schematic diagram is shown in Figure 2.91.

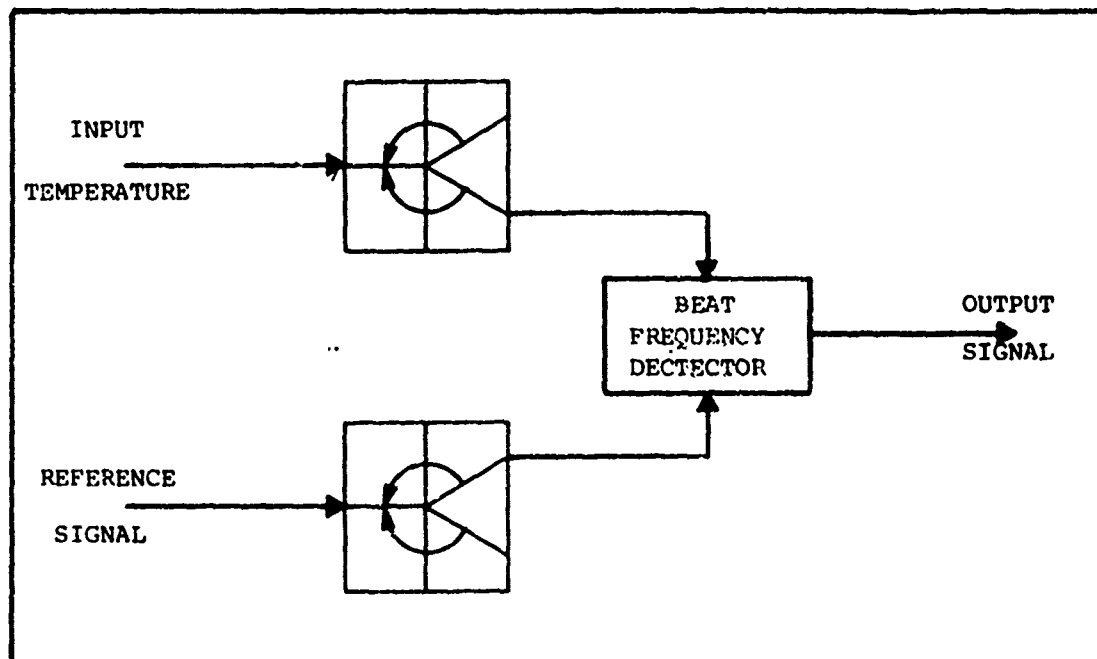

FIGURE 2.91 TYPICAL TEMPERATURE SENSOR DIAGRAM

2.5.1 Flow Resistance Sensor

Figure 2.92 depicts the generalized schematic diagram of a flow resistance type of temperature sensor. With this concept, the flow resistance is measured across the laminar section. It has been demonstrated that the pressure drop across this section is inversely proportional to the temperature. It should be noted, however, that this type of device effectively obeys this premise only in a specific operating regime. At an extremely low temperature, the pressure drop begins to increase with temperature. It should be noted also that this sensor is basically a high impedance unit, thus requiring signal amplification. Its net time response is a function of the total capacitance of the lines used to measure the pressure drop and the flow rate through the sensor itself.

2.5.2 Bridge Type Sensor

A modification of the basic flow resistance type of temperature sensor is known as the bridge type temperature sensor. Flow resistance elements are formed in a bridge network similar to that shown in Figure 2.95. They utilize the linear and non-linear characteristics of laminar and turbulent pressure drops in opposing bridge arms. Although some bridge type temperature sensors have been used by commercial manufacturers in specialized systems designed for specific applications, no commercial devices of this type are presently available as off-the-shelf units.

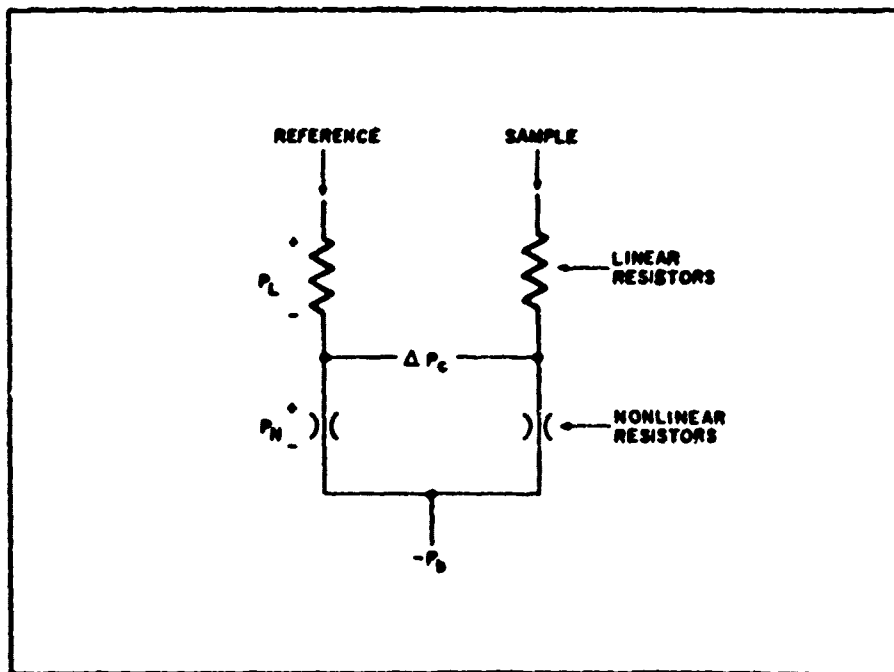

FIGURE 2.95 BRIDGE TYPE FLOW TEMPERATURE SENSOR DIAGRAM

2.5.3 Oscillator Type Sensor

The operation of an oscillator type of fluidic temperature sensor is based on the premise that the frequency of a fluid oscillator depends on the speed of wave propagation in the fluid medium. Since this wave propagation is a function of gas temperature, the frequency of oscillation, therefore, is a direct measure of the temperature differential or change. To provide an accurate reference and thus ensure that the oscillator frequency be independent of pressure, the sensor must be operated under essentially "choked" conditions. The basic bistable fluid oscillator is shown in Figure 2.96. Its method of operation is as follows. As the jet exits out of port A, some flow is returned through the feedback loop C, causing the jet to switch to the opposite side. The jet, now exiting out of side B, returns a portion of the fluid through the right feedback loop, thus causing the jet to again switch back, completing the cycle.

It can be shown that the period of oscillation of a fluidic temperature sensor is directly proportional to the length of one loop of the feedback and inversely proportional to the jet velocity and speed of wave propagation. Tests have shown that to increase the sensitivity of the device it is necessary to increase the frequency (i.e., reduce the feedback loop) at which the oscillator is operating. The shortest possible feedback loop for an oscillating type of sensor consists of an internal resonance chamber (or cavity) rather than the external ducts. With this type of arrangement, however, edgetone frequencies about the splitter are generated, and these are also effected by the temperature of the fluid. Response times for this device are claimed in the order of 0.01 second.

2.6 Concentration Sensors

As defined here, concentration sensors are those devices that are used to monitor the percentage "mixture" of a gas. These devices are configured in one of three basic designs: the resistance bridge, the vortex, and the oscillator. Tests have shown that all have relatively low threshold sensitivity to a contaminant gas, but require amplification of their outputs to provide a useful signal.

2.6.1 Resistance Bridge Concentration Sensor

The resistance bridge concentration sensor is by far the simplest. Basically, it consists of both linear (viscosity dependent) and nonlinear (density dependent) resistors connected in a bridge circuit similar to that shown in Figure 2.100. The resultant differential pressure signal is proportional to the unknown concentration of the "used" gas. Experiments have shown that this type of device is quite sensitive to small concentrations (in the order of 100 parts per million) and the device has an output that is extremely linear. A basic variation of the resistance bridge type of circuit is the replacement of one of the resistors with one or more vortex type resistors. Since the resistance of the vortex resistor is due to angular momentum rather than viscosity effects, it is less affected by temperature changes. Consequently, a large differential pressure output depending upon temperature will be delivered by the amplifier.

FIGURE 2.102 AVAILABLE DATA-CONCENTRATION SENSOR-HDI.

2.6.2 Vortex Type Concentration Sensor

The vortex type concentration sensor operates on the principle of comparing a pressure differential of two fluid samples. One sample, which is a reference, is allowed to pass directly through a vortex chamber. The other sample is passed over a "scrubber" or catalyst bed to remove the desired gaseous element. The intensity of the vortex is a linear function of the density difference of the two samples. An angle of attack sensor provides the output signals.

Investigations have shown that practical designs have an expected time delay between 0.1 and 15 seconds and that linearity is achievable over select ranges that are dictated by the sizing of the unit. A schematic diagram is shown in Figure 2.103.

2.6.3 Oscillator Concentration Sensor

The same basic type of device employed for oscillator temperature sensing is also employed for an oscillator concentration sensor. Claims are that the edgetone oscillator has a higher gain and better signal to noise ratio than that obtained from feedback loop type bistable element oscillators. The basic configuration is shown in Figure 2.105. For proper operation, the sensor relies upon a catalyst or "scrubber" to effectively change the density of the fluid being analyzed and thus provides a differential beat frequency. Tests have shown that the output is extremely linear over a 0 to 10 percent concentration range. At this time, no commercial devices of this nature are available.

2.7 Miscellaneous Sensors

In addition to the specific sensors previously discussed, a number of sensors have been developed for other applications. Typically, these devices fall into the general categories of densitometers, flow meters, pressure transducers, and attitude gyros. Many of these devices are more fluidic than flueric in nature, because they contain one or more moving parts to supplement the sensing function.

2.7.1 Densitometers

The fluid densitometer is used for primary sensing of the density measurement of fluids. As shown in the schematic diagram in Figure 2.110, its operation is based upon the interaction of free turbulent jets. Its principle of operation is as follows.

Basically, the unit is comprised of two chambers, a reference chamber and a measurement chamber. Identical turbulent jets issue from each of two nozzles into their respective chambers, and each jet impinges upon a receiver port. The reference chamber has only a small exit port and essentially becomes a capacitance when filled with the supply fluid. The measuring chamber is open to ambient pressure, and thus has an infinite capacitance. Since the pressure profile of the jet must change as a function of the density of the material, measurement of the pressure differential at the output demonstrates that the resulting signal is logarithmical and varies as a function of both the temperature and pressure of the fluid. Only one device of this type currently exists.

2.7.2 Attitude Gyros

There are two basic types of fluidic gyros currently designed and tested. Both are hybrids in that they employ some type of mechanical moving element to obtain satisfactory performance. The first, a two-axis pneumatic pick-off (TAPP), consists of a rotor supported on a gas bearing. This rotor is the only mechanical moving part of the entire gyroscope. The remaining components include a gas supply bottle, a Squibb igniter device, an internal regulator, a two-axis pneumatic pick-off, and a fluidic summing module. It is available in both analog and digital configurations. Claims are that this type of gyro can obtain satisfactory performance when subjected to over 1200 G's.

A slightly different type of attitude gyro employs the same basic principle, but includes a device for automatic sequencing for start-up and uncaging. This is shown in Figure 2.115. With this concept, the natural rotor boundary layer is used as a power source for the sensor. These types of devices are available only on special order from select manufacturers, and none are available as commercial off-the-shelf items.

2.7.3 Flow Meters

There are three basic types of fluid flow meters (or velocity sensors) currently available. The first employs a free jet traversing between a supply jet and two total head pickup tubes or receivers. The operation of the sensors is dependent upon the jet entrainment of the surrounding fluid, which causes the jet issuing from the nozzle to be deflected to one or the other of the pickup tubes. By monitoring of pressure differential across the pickup tubes, it can be shown that the cross flow of the measured velocity is directly proportional to the pressure differential. Accuracies are claimed in the order of 2% of maximum reading, and experiments have shown that the dependency of differential pressure varies linearly with cross flow air velocity.

The second type of fluidic flow meter employs a basic fluidic oscillator such as shown in Figure 2.120. With this concept, oscillations are detected by a flush mounted sensor (electromagnetic) and are amplified by electronics to provide a digital pulsed output. Basically, the device is nothing more than a fluidic oscillator with the feedback passage essentially controlling the frequency of oscillation for a given flow velocity. Experiments have shown that the sensor yields a relatively noise free signal with accuracies claimed in the order of $\pm 0.2\%$ of the actual flow rate. The third type can also be considered an oscillator, since it employs an ultrasonic means of measuring vortex shedding about a submerged strut.

2.7.4 Pressure Ratio Sensor

The pressure ratio sensor is a device that can be used to monitor a preset differential pressure. There are several variations, but most consist of a two-part mechanism having both a fluidic to mechanical pressure sensing section and a mechanical to electrical transducer. Only one commercially available pressure ratio sensor has no moving mechanical parts. It employs a vortex "whistle" and utilizes a piezoelectric crystal to monitor the vortex "whistle" frequency.

The mechanical type is composed of two stages of fluidics: a receiver and an amplifier. Typically, each is suspended on two soft diaphragms to form a leakless push-pull piston. Manufacturers claim accuracy to $\pm 3.5\%$ of reading and time of response in the order of 15 ms. Several versions of these devices are shown in Figure 2.129.

2.7.5 Electronic/Fluidic Transducer

This device can be considered either a sensor or an interface device. It employs a bistable amplifier with two cylindrical heating wires of equal diameter located in the power nozzle of the amplifier. The principle of operation is depicted in Figure 2.138. Two heating wires are positioned so that they are symmetrical with respect to the centerline of the channel. If the velocity profile upstream of the wires is uniform (and no heat is transmitted to either wire), then the downstream velocity profile also remains symmetrical with respect to centerline of the channel (see Figure 2.138a). When a current is passed through wire A, its temperature increases rapidly, and the resistance to the flow of fluid around wire A increases (i.e., the wire's effective diameter increases). Thus, more flow is diverted into the region around wire B, resulting in the velocity profile shown in Figure 2.138b. The amplifier can also operate as a bistable element since it is provided with standard controls. Claims of manufacturers include the fact that the unit will respond in about 50 ms and is insensitive to accelerations.

3. CONCLUSIONS

Material presented in this state-of-the-art survey was heavily oriented toward providing the basic geometric and operating data required for a design engineer to utilize fluidic technology. Although full cooperation was not received from all organizations who received a copy of the questionnaire, the material presented herein reveals that fluidic sensing technology is indeed state-of-the-art and can be employed in many different types of circuits.

This survey, however, also served a second purpose. It may not be all-inclusive, but it does demonstrate two important results.

- A considerable number of sensors are still basically in the R&D stage, and thus require venture capital and/or IR&D funds to further their development.
- There are a number of areas where new devices are warranted since fluidic sensing offers a promise that has not yet been realized.

With regard to the latter statement, it has been demonstrated that the equipment reliability is much higher with fluidics than with competing electrical or electrical/mechanical elements. Furthermore, their costs have now become competitive, and with the development of new types of elements (or variations of existing elements), accuracies and reliability are constantly being improved.

FLUIDIC SENSOR QUESTIONNAIRE

LORELEI CORPORATION

FLUIDIC SENSOR QUESTIONNAIRE

GENERAL INSTRUCTIONS

Most questions presented herein are self explanatory and require nothing more than a check-off in the space provided. However, the following detailed instructions are intended to assist you in responding to the following specific items.

- Item A.6. Indicate your source of information for filling out this questionnaire.
- Item B.1. If available, list the manufacturer's part number. If there is no part number, list as A,B,C,D to provide correlation with questions B.2. and E.4. Also be sure to indicate units (inch, cm, etc.)
- Item C.8. If the performance of the sensor changes with scaling (e.g., loss of gain with increase in size) explain and use a separate questionnaire for each size.
- Item C.16. Indicate the result of secondary effects on the performance of the sensor (e.g., temperature on an acceleration sensor, pressure on a temperature sensor, etc.)
- Items C.19,20,21. Indicate how the reliability figures were obtained and if tests were conducted, what parameters were controlled.
- Item D.5. Explain if and how the sensor causes any change in the quantity being measured (e.g., pressure drop, temperature increase, etc.)

If additional space is needed, the form can be copied on standard size paper. Further, if any question is not applicable to your sensor, put (NA) in the appropriate space; and if the answer is unknown, put in a question mark (?). For those items flagged by an asterisk (*) we would appreciate additional information in the form of charts or graphs. Lastly, please attach a photograph (or preferably a cutaway diagram) to the completed questionnaire prior to mailing to: LORELEI Corporation, 615 South Frederick Avenue, Gaithersburg Maryland 20760, Attn:LMS.

Thank you for your interest and co-operation in this program.
